2008 February 2

**Abstract.** We have used the Giant Meterwave Radio Telescope (GMRT) to measure the Galactic HI 21-cm line absorption towards 102 extragalactic radio continuum sources, located at high ( $|b| > 15^\circ$ ) Galactic latitudes. The Declination coverage of the present survey is  $\delta > \sim -45^\circ$ . With a mean rms optical depth of  $\sim 0.003$ , this is the most sensitive Galactic HI 21-cm line absorption survey to date. To supplement the absorption data, we have extracted the HI 21-cm line emission profiles towards these 102 lines of sight from the Leiden Dwingeloo Survey of Galactic neutral hydrogen. We have carried out a Gaussian fitting analysis to identify the discrete absorption and emission components in these profiles. In this paper, we present the spectra and the components. A subsequent paper will discuss the interpretation of these results.

**Key words:** ISM: clouds, kinematics and dynamics – Radio lines: ISM.

## 1. Introduction

The distribution atomic hydrogen in the Galaxy and its physical properties have been extensively studied. Soon after the discovery of the HI 21-cm line, a number of single dish HI surveys were conducted (See Burton, 1988 for a useful compilation of the early HI surveys). The single dish HI absorption spectra are limited by the errors due to the variation of HI emission intensity over the angular scales smaller than the telescope beam. Interferometric surveys are a better alternative for HI absorption studies. An interferometer rejects the low spatial frequencies where HI emission is dominant, resulting in reliable absorption spectra. There have been

<sup>§</sup>e-mail:srini@rri.res.in

a number of interferometric HI absorption studies, often supplemented by single dish observations to measure the HI emission.

The early HI 21-cm line absorption and emission studies led to the emergence of a global picture of the interstellar medium (Clark, Radhakrishnan & Wilson, 1962; Clark, 1965). These and later studies paved way for the models of the interstellar medium of the Galaxy. Field, Goldsmith & Habbing (1969) modeled the ISM as cool dense concentrations of gas, often referred to as “interstellar clouds” (the Cold Neutral Medium or CNM) in pressure equilibrium with a warmer intercloud medium (the Warm Neutral Medium or WNM). While this initial model of the ISM has been refined considerably by later studies (Wolfire et al, 1995), the basic picture of the ISM with cold diffuse clouds and a warmer intercloud medium has survived. The spin temperature of the cold clouds which constitute the CNM was estimated to be  $\sim 80$  K and that of the WNM to be  $\sim 8000$  K. The cold clouds manifest as narrow Gaussian features with typical velocity dispersions of a few  $\text{km s}^{-1}$  in both HI emission and absorption profiles. The intercloud medium, on the other hand, is identified with broad Gaussian features with typical velocity dispersions  $\gtrsim 10 \text{ km s}^{-1}$ . The intercloud medium is usually detected in emission, since the HI absorption in the warm gas is very weak. We summarize the results from some of the important surveys below.

Radhakrishnan et al (1972a, 1972b) used the Parkes Interferometer to study the HI absorption towards 35 extragalactic radio sources, in the Galactic latitude range  $6^\circ \leq |b| \leq 74^\circ$  and 53 Galactic radio sources in the lower Galactic latitudes, mostly located at  $|b| < 2^\circ$ . In addition, the Parkes 64 m telescope was used to obtain the HI emission towards all these directions. The velocity resolution of these observations was  $2.1 \text{ km s}^{-1}$ . The rms noise in the HI optical depth profiles varied from  $\sim 0.01$  to  $> 0.1$ , depending on the flux density of the background source. They concluded that the HI absorption features are arising in discrete concentrations of gas with a spin temperature in the range  $60 - 80$  K. They also derived the number density of these features to be  $\sim 2.5$  per Kpc (Radhakrishnan & Goss, 1972). The number of such concentrations of gas for a given optical depth  $\tau$  was  $\propto e^{-\tau}$ . Lack of absorption in the intercloud medium, which was identified as the wide “shoulders” in HI emission profiles, enabled them to put a limit of  $> 750$  K for the spin temperature of this gas.

Dickey & Benson (1982) used the NRAO 300 ft and 140 ft telescopes as an interferometer to detect absorption in the 21-cm line towards 64 radio continuum sources. The HI emission profiles were obtained using the 300 ft telescope alone. These sources were both Galactic and extragalactic and spread over a range of latitudes  $0^\circ \lesssim |b| \lesssim 70^\circ$ . They have produced HI absorption profiles with an rms optical depth in the range  $\sim 0.007 - \sim 0.16$ , with a velocity resolution ranging from  $1.3 - 5.3 \text{ km s}^{-1}$ . Among the main results of this study was the realization that for lower Galactic latitudes ( $|b| \lesssim 15^\circ$ ), HI emission surveys using single dish telescopes would miss a significant amount of gas ( $\sim 40\%$ ) due to HI self absorption, wherein the cold HI gas in the foreground absorbs the HI line emission from the background gas. They also found more HI gas with lower spin temperature ( $100 \lesssim T_S \lesssim 150$  K)

at lower latitudes ( $|b| < 2^\circ$ ) as compared to the previous HI line surveys. They concluded that such a behaviour is the result of velocity blending.

Mebold et al (1981) carried out an HI absorption survey towards 69 sources in the range  $0^\circ \lesssim |b| \lesssim 80^\circ$  using the NRAO 3-element interferometer. They obtained the corresponding HI emission using the Effelsberg 100 m telescope, the 91 m Green Bank telescope or the 64 m Parkes telescope. The velocity resolution of these profiles were in the range  $0.42 - 3.3 \text{ km s}^{-1}$ . These profiles, on an average, had an rms in HI optical depth  $\gtrsim 0.05$ . They found most of the HI absorption features to have a spin temperature in the range 20 to 140 K. For the HI absorption data at  $|b| > 15^\circ$ , they found indications for a bimodal distribution in the radial velocity distribution of absorbing features. However, since the number of components at higher radial velocities were small, they were unable to study its significance.

Till recently, the Very Large Array (VLA) used to be the only instrument with a collecting area comparable with large single dish telescopes. The survey by Dickey et al. (1983) using the VLA is limited to lower Galactic latitudes ( $|b| < 10^\circ$ ). Moreover, the optical depth detection limit for this survey is  $\sim 0.1$  ( $3\sigma$ ). From the various HI absorption surveys carried out so far (Radhakrishnan et al., 1972a, 1972b; Mebold et al., 1981; Dickey & Benson, 1982 ; Dickey et al., 1983), more than 600 absorption spectra are available, but the optical depth detection limits of more than 75% of these are above 0.1. From the available results, the cloud population observed in HI absorption seem to have a Gaussian random velocity distribution. The dispersion in the random velocities of HI absorption features is  $\sim 7 \text{ km s}^{-1}$  (Dickey & Lockman, 1990, and references therein).

The low optical depth regime of Galactic HI is largely unexplored except for the HI absorption studies using the Arecibo reflector by Dickey et al (1978) and more recently by Heiles & Troland (2003a, b). Dickey et al measured HI absorption and emission towards 27 extragalactic radio continuum sources located at high and intermediate Galactic latitudes ( $|b| > 5^\circ$ ). The rms optical depth in their spectra were typically  $\sim 0.005$ . In many of the profiles the systematics in the band dominate the noise in the spectrum. As we noted earlier, these observations are not impervious to HI emission fluctuations introducing errors in the absorption profile (Dickey & Lockman, 1990). Radhakrishnan & Goss (1972) found the number of HI absorption features for a given optical depth,  $\tau$  to be proportional to  $e^{-\tau}$ . However, the data by Dickey et al (1978) as well as the later survey using the Green Bank Interferometer (Mebold et al, 1982) indicated that for  $|b| > 15^\circ$  this dependence is steeper than  $e^{-\tau}$ . This trend was explained as due to increase of low optical depth features with increasing angular and velocity resolution (Mebold et al, 1982). Dickey et al (1978) also noted that the velocity distribution of HI absorption features is dependent on the optical depth. For the optically thin clouds ( $\tau < 0.1$ ), the velocity dispersion was  $\sim 11 \text{ km s}^{-1}$ , whereas for the optically thick clouds ( $\tau > 0.1$ ) this value is  $\sim 6 \text{ km s}^{-1}$ . Heiles & Troland (2003a, b) analysed HI absorption and emission profiles toward 79 lines of sight. A good fraction of these directions (66 out of 79) were at Galactic latitudes  $|b| > 10^\circ$ . They found evidence for an excess of low column density ( $N_{\text{HI}} < 5 \times 10^{19} \text{ cm}^{-2}$ ) CNM components.

## **2. Motivations for the present survey**

The prime motivation for the present survey was to obtain sensitive HI absorption measurements at high Galactic latitudes and to study the random velocity distribution of HI clouds. Although there exist extensive data on Galactic HI absorption, there is a lack of sensitive HI absorption studies. There are indications that the low optical depth features ( $\tau < 0.1$ ) form a distinct class (Dickey et al, 1978; Mebold et al 1982; Heiles & Troland 2003b), with larger velocity dispersion. The dependence of HI column density and optical depths of these clouds on their random velocities are not well studied. Our aim was to investigate the nature of low optical depth HI features in the Galaxy and to estimate their velocity distribution. One of the difficulties encountered in studying discrete components in the HI 21-cm line profiles in the Galactic plane is the plethora of absorption lines. Larger path length through the disk of the Galaxy results in larger number of absorption components. In such cases, the available techniques often result in more than one possible solution for the parameters of individual features. Moreover, the observed radial velocities are usually the sum of components arising from random motion and the differential rotation of the Galaxy. The distances to the absorbing clouds are seldom known. Hence the systematic component in the observed radial velocity arising from Galaxy's rotation is unknown. Therefore, the lower Galactic latitudes are not suitable for a survey to search for low optical depth components and to study the random velocity distribution of interstellar clouds. We have chosen a lower cutoff of  $15^\circ$  for the Galactic latitude in our observations.

Most of the HI gas at higher latitudes is observed only in HI emission (Dickey & Lockman, 1990, and references therein). The HI emission profiles often show components at velocities that cannot arise from Galactic rotation. The existing surveys of HI absorption indicate that there is very little absorption in directions above a latitude of  $\sim 45^\circ$ , down to optical depths  $\sim 0.01$  (Dickey et al, 1978). But, there are indications that HI gas layer of the Galaxy extends to several kpc (Albert, 1983; Lockman & Gehman, (1991); Kalberla et al, 1998). A more sensitive HI absorption search is required to understand the nature of this gas and to characterize it.

We present here the HI absorption measurements with the Giant Metrewave Radio Telescope (GMRT) towards 102 extragalactic radio continuum sources located at intermediate and high latitudes. The present survey, with an rms detection limit of 0.003 in HI optical depth is at least a factor of 5 more sensitive than the existing interferometric surveys and is comparable with the sensitivities achieved in the single dish HI surveys using the Arecibo telescope (Dickey et al, 1978; Heiles & Troland, 2003a). An overview of the GMRT is given in the next section. The strategy for selecting the sources is outlined in section 4 and the details pertaining to the observations are given in section 5. A brief description of the data analysis is given in section 6 and section 7 describes a sample HI absorption profile. The list of observed sources is presented in Appendix A, the HI line profiles towards

these sources are given in Appendix B and Appendix C lists the discrete HI features identified from each of these profiles.

### 3. The Giant Meterwave Radio Telescope

The Giant Meterwave Radio Telescope (GMRT) consists of 30 fully steerable dishes, of 45 meter diameter with a maximum baseline of 25 km (Swarup et al., 1991). The aperture efficiency of the dishes is  $\sim 40\%$  in the 21cm band, which implies an effective collecting area of  $\sim 19000 \text{ m}^2$ . The full width at half maximum of the primary beam primary beam is  $\sim 25'$  and that of the synthesized beam is  $\sim 2''$  (uniform weighting) at 1.4 GHz. The 21 cm receiver is a wide band system covering the frequency range 900 – 1450 MHz. It is a prime focus uncooled receiver with a characteristic system temperature of  $\sim 70\text{K}$ . The 21cm system has four sub bands, centered at 1060, 1170, 1280 and 1390 MHz respectively, each with a 3 dB bandwidth of 120 MHz. At the time when these observations were carried out, this telescope was equipped with an FX correlator providing 128 channels per polarization per baseline. A baseband bandwidth ranging from 16 MHz down to 64 kHz variable in steps of 2 can be chosen.

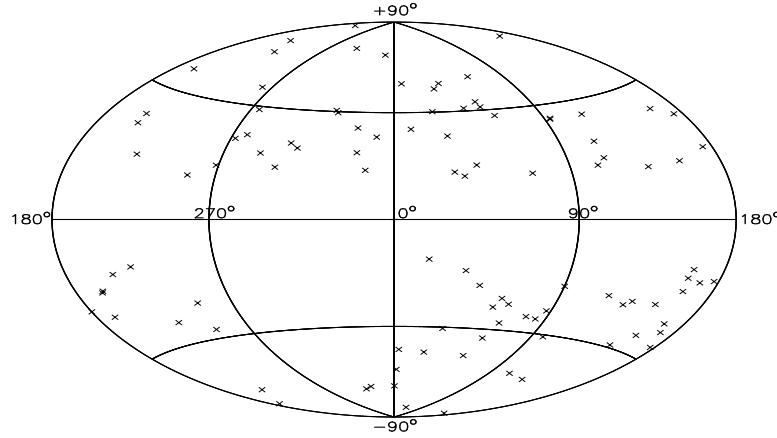

### 4. Source selection

In selecting the sources, we have used a lower cutoff in flux density of 1 Jy at 20cm wavelength. This was to ensure that we reach an rms in HI optical depth  $\sim 0.003$  within an observing time  $\lesssim 1$  h. In order to obtain a sample of these bright sources uniformly distributed all over the sky we used the VLA calibrator manual as the basic finding list. A list of 102 point sources, unresolved in the VLA B array configuration, with their Galactic latitude  $|b| \geq 15^\circ$  were selected. Figure 1 shows the distribution of the program sources in the sky. The list of sources is given in Appendix A.

To supplement the absorption spectra, HI emission profiles were extracted from the Leiden-Dwingeloo all sky survey of Galactic neutral hydrogen (LDS, Hartmann & Burton, 1995). This survey used the 25 meter Dwingeloo telescope to map the sky in HI emission. The full width at half maximum of the primary beam of the Dwingeloo telescope is  $\sim 36'$ . The geographic latitude of the Dwingeloo telescope is  $\sim +53^\circ$  and that of the GMRT is  $\sim +19^\circ$ . Therefore some of the lines of sight in the southern hemisphere observed with the GMRT are not accessible to the Dwingeloo telescope.

### 5. Observations

The HI absorption observations were carried out using the GMRT during March–April 2000, and April–June 2001. On an average, we used  $\sim 20$  antennas in the final analysis, though the actual number varied from 12 to 25. We used a baseband

**Figure 1.** The distribution of program sources in Galactic co-ordinates. The fourth Galactic quadrant ( $270^\circ < l < 360^\circ$ ) is not fully accessible for the GMRT, since this region is mainly in the southern equatorial hemisphere

of width 2 MHz, which translates to  $\approx 422 \text{ km s}^{-1}$  in velocity and a resolution of  $\sim 3.3 \text{ km s}^{-1}$ . The centre of the band was set at 1420.4 MHz. We used one of the VLA primary flux density calibrators (3C48/3C147/3C286) for setting the flux density scale. Since all the program sources were unresolved by the GMRT, they also served as phase calibrators. Bandpass calibration was carried out once every two hours for 10 minutes using 3C286, towards which no HI absorption was detected down to an rms in optical depth of  $\tau_{\text{HI}} \sim 0.002$ . On source integration time ranged from 10 to 60 minutes, depending on its strength. The rms sensitivity in optical depth varied from 0.002 to 0.008 towards different sources, with a mean value  $\sim 0.003$ . A summary of the observational setup is given in Table 1.

## 6. Data Analysis

The data were analysed using the Astronomical Image Processing System (AIPS) developed by the National Radio Astronomy Observatory. The observing band was found to be free from any kind of interference. The resulting data set consisted of 102 image cubes. The full width at half maximum of the synthesized beam width was in the range  $\sim 6''$  to  $\sim 25''$ , depending on the number and locations of available antennas. Continuum subtraction was carried out by fitting a second order baseline to the line-free channels in the visibility domain and subtracting the best fit continuum from all the channels. Such a second order fit to the spectral baseline can result in the removal of broad and shallow absorption features. From the nature

**Table 1.** The Observational Setup.

Telescope	GMRT
System temperature	~70 K
Aperture efficiency	~40%
Baseband bandwidth	2.0 MHz
Number of channels	128
Velocity resolution	3.3 km s <sup>-1</sup>
On source integration time	~10 to 60 minutes
rms noise (1 hr Integration time)	~2 mJy beam <sup>-1</sup> channel <sup>-1</sup>

of the baselines fitted to the present dataset, we infer that any spectral features with FWHM  $\gtrsim 50$  km s<sup>-1</sup> and  $\tau_{\text{HI}} \lesssim 0.03$  would not be detected. However, the main aim of the present survey is to study the narrow absorption lines arising from the diffuse features in the CNM and the FWHM of such features are usually  $\lesssim 10$  km s<sup>-1</sup>. The second order fit also helps to achieve a better spectral dynamic range over the 2 MHz bandwidth. The resulting spectral dynamic range was  $\sim 500$ . However, for a few lines of sight, the bandpass errors were much larger and only a limited part of the observing band was found to be usable. To study the individual HI absorption components multiple Gaussian profiles were fitted to the absorption line spectra using the Groningen Image Processing System (GIPSY).

For an optically thin HI gas, the radiative transfer equation has a solution of the form (Spitzer, 1978)

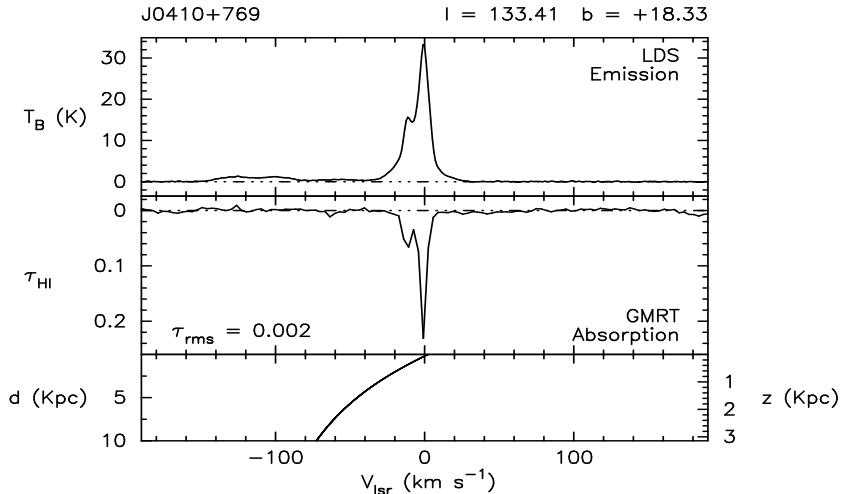

$$T_B = T_S(1 - e^{-\tau}) \quad (1)$$

where  $T_B$  is the brightness temperature,  $T_S$  is the spin (excitation) temperature and  $\tau$  is the optical depth of the HI 21-cm line. Hence, knowing the line brightness temperature  $T_B$ , which is obtained from the HI emission profiles, and the optical depth  $\tau$ , obtained from HI absorption, one can estimate the spin temperature  $T_S$  of HI gas.

Apart from the new HI absorption measurements with the GMRT, we have extracted the HI emission profiles towards these lines of sight (if available) from the Leiden-Dwingeloo sky survey (Hartmann & Burton, 1995). We have used Gaussian fitting to the spectra to separate the profiles into discrete components. The HI emission profiles were Hanning smoothed over two channels, with a resulting velocity resolution of  $\sim 2$  km s<sup>-1</sup>. It is well known that the HI emission features are broader than the corresponding absorption features. This difference in the velocity width usually range from 0 – 5 km s<sup>-1</sup> (Radhakrishnan et al 1972b). It is also known that the wider HI emission features (FWHM  $> 20$  km s<sup>-1</sup>) arise in the warm neutral medium (WNM) (Radhakrishnan et al, 1972b). To identify the HI emission and absorption lines that arise from the same cloud, we have adopted the following considerations:

- The central velocities of the HI emission and absorption features are within the channel width,  $\sim 3.3 \text{ km s}^{-1}$ , of the GMRT observations, and
- The difference between the widths of emission and the corresponding absorption line is less than  $\sim 5 \text{ km s}^{-1}$

If both the above conditions were satisfied, we assume the features to arise from the same cloud. The second criterion excludes those instances where the velocity of a CNM absorption line match that of a WNM emission component. We have used the fitted values of  $\tau$  and  $T_B$  to calculate the spin temperatures of HI features which are identified in both HI emission and absorption profiles. In those cases, where no HI absorption feature was detected from our survey corresponding to the HI emission feature in the LDS survey data, we have estimated the lower limit for the spin temperature of the gas.

**Figure 2.** The HI optical depth spectrum from the GMRT towards one of the 102 sources (middle panel) and the corresponding HI brightness temperature profile from the Leiden-Dwingeloo survey (top panel). The lower panel is the Galactic rotation curve for the given line of sight obtained from the Galactic rotation model (Brand & Blitz, 1993). The heliocentric distance as a function of radial velocity is labeled on the left of the lower panel and the corresponding height above the mid-plane of the Galaxy is labeled on the right side.

## 7. The Spectra

Figure 2 is a sample spectrum of HI optical depth and the corresponding HI emission profile. In the figure, The lower panel is the Galactic rotation curve for the given line of sight obtained from the Galactic rotation model by Brand & Blitz (1993). We have used  $R_0 = 8.5 \text{ Kpc}$  as the Galacto-centric distance and  $\Theta_0 = 220$

km s<sup>-1</sup> as the solar orbital velocity around the Galactic centre. The rest of the spectra are given in Appendix B and the summary of the Gaussian fitting results are given in Appendix C. In all we have obtained 126 spectral components in HI absorption from GMRT and 478 components in HI emission from the LDS survey. The fitted parameters for the discrete components in HI absorption and emission were used to estimate the spin temperature of the respective features. A detailed analysis and interpretation of these spectra are given in an accompanying paper (Mohan et al, 2004; this volume).

**Acknowledgements:**

We wish to thank C.R. Subrahmanya for useful discussions related to the GMRT offline software. We thank the referee, Miller Goss, for detailed comments and constructive criticisms resulting in an improved version of this paper. We thank the staff of the GMRT who made these observations possible. The GMRT is operated by the National Centre for Radio Astrophysics of the Tata Institute of Fundamental Research. This research has made use of NASA's Astrophysics Data System.

## Appendix A: The Source list

The list of sources observed with the GMRT. The sixth column gives the rms optical depth in the HI absorption spectra and the last column lists the observed flux densities of the respective sources.

## Appendix B: The Spectra

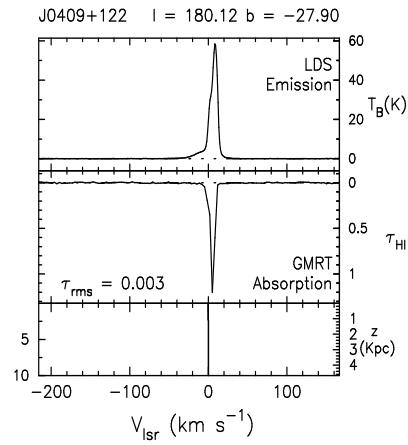

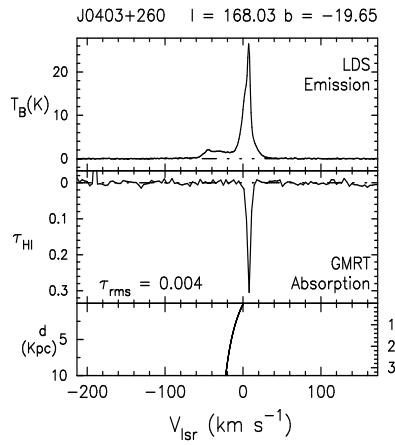

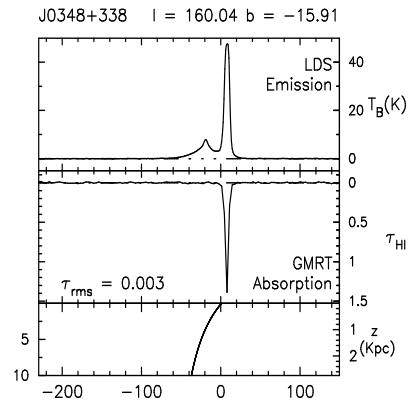

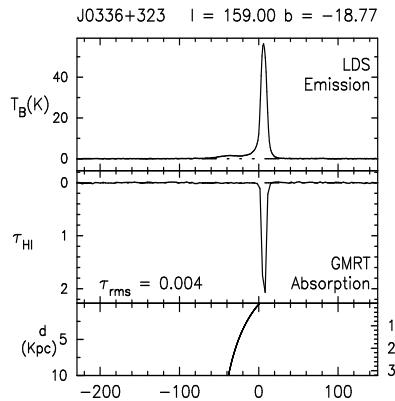

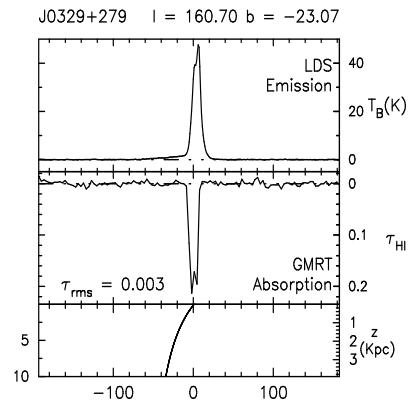

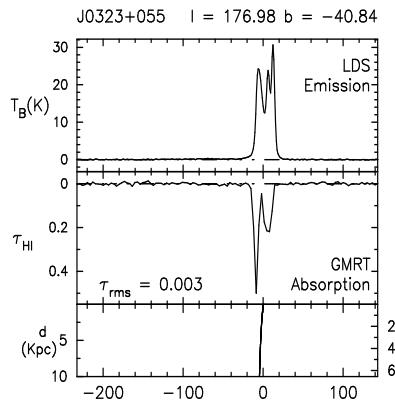

In this Appendix, we present the HI optical depth profiles obtained from the high latitude Galactic HI absorption survey using the GMRT along with the HI emission profiles in the respective lines of sight from the Leiden-Dwingeloo survey of Galactic Neutral hydrogen (if available). The figures are arranged in order of increasing Right Ascension. The spectra are labeled by the radio continuum source name in J2000.0 co-ordinates (top left) and its Galactic co-ordinates (top right).

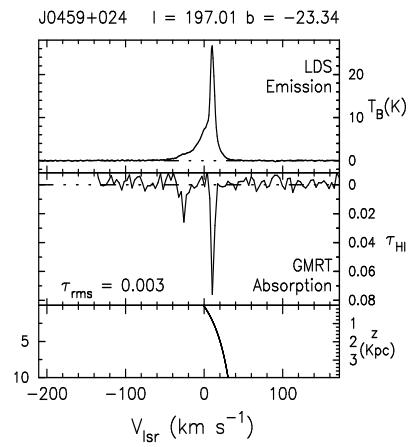

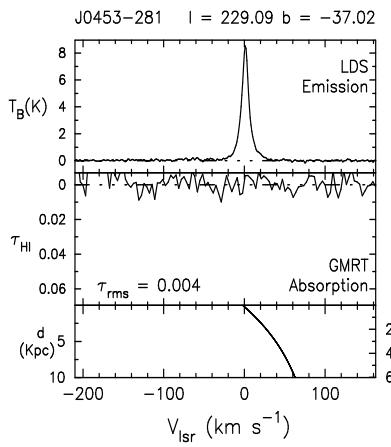

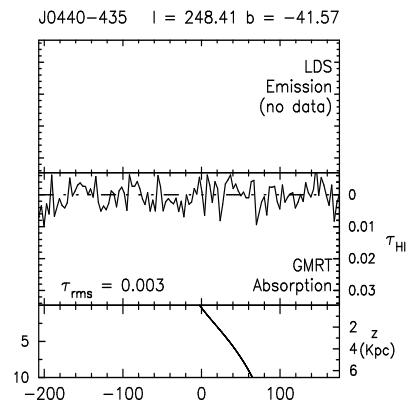

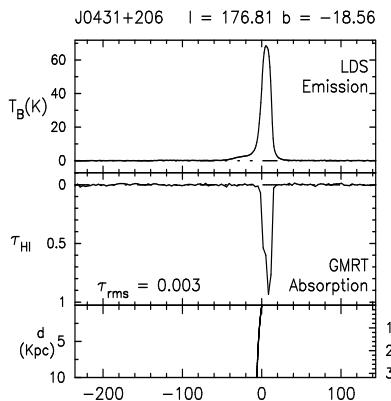

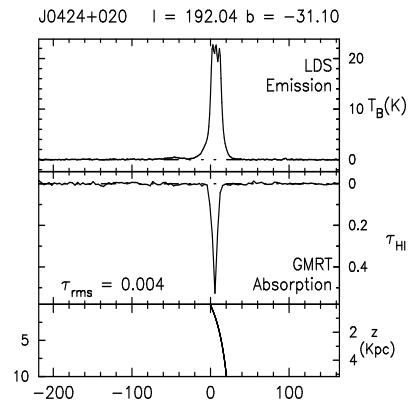

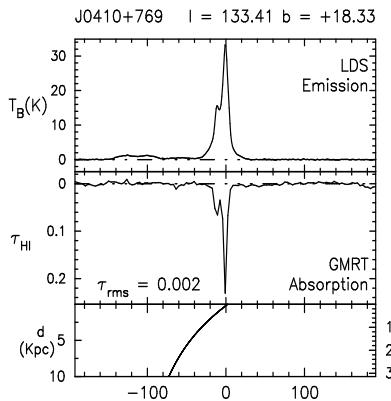

For each of the figures, the HI emission profile from the Leiden-Dwingeloo Survey is shown in the top panel and the HI optical depth profile from the GMRT is shown in the middle panel. The lower panel is the Galactic rotation curve for the given line of sight. The heliocentric distance as a function of radial velocity ( $V_{lsr}$ ) is labeled on the left of this panel and the corresponding height above the mid-plane of the Galaxy is labeled on its right side. For a few lines of sight, only the reliable part of the observing band is shown.

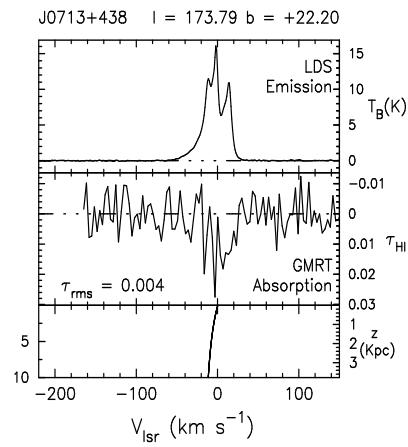

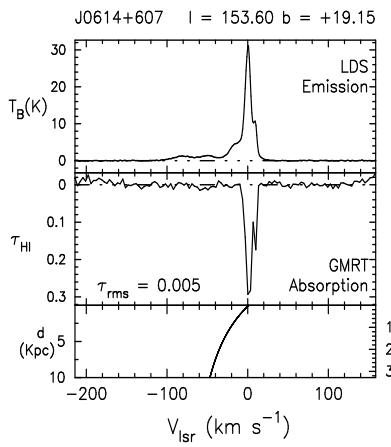

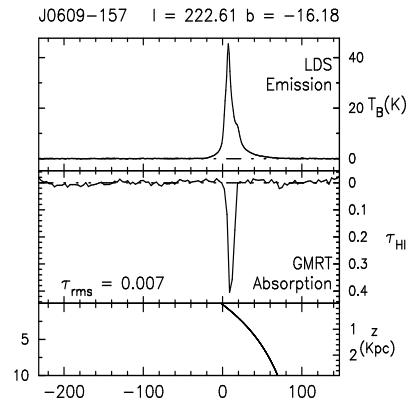

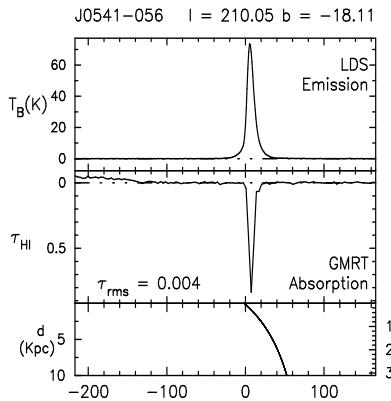

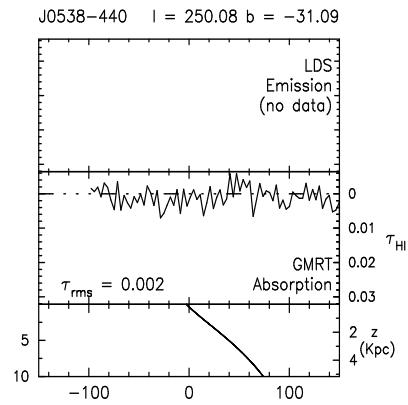

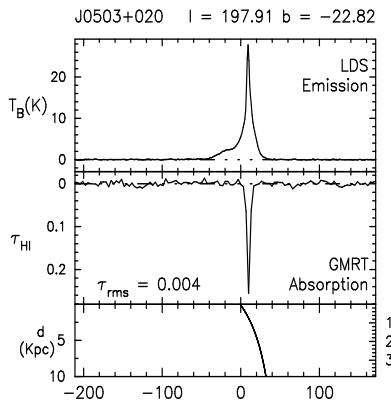

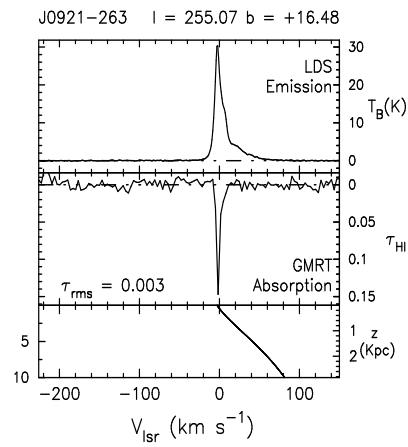

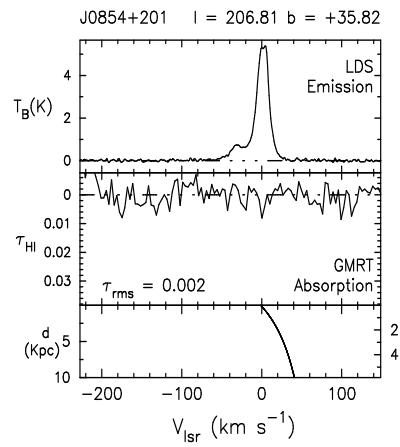

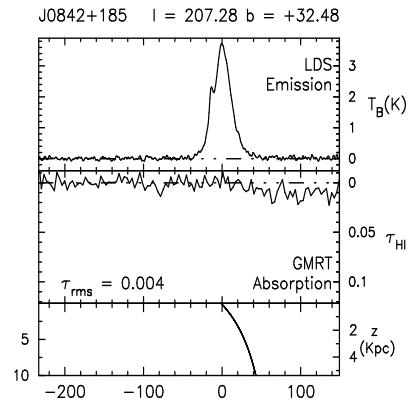

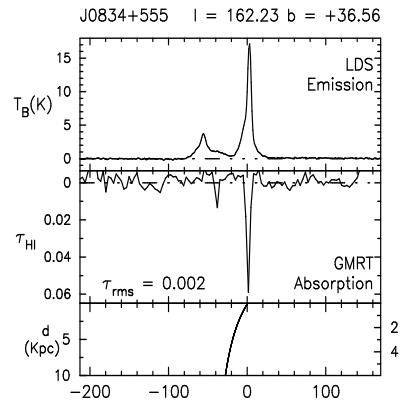

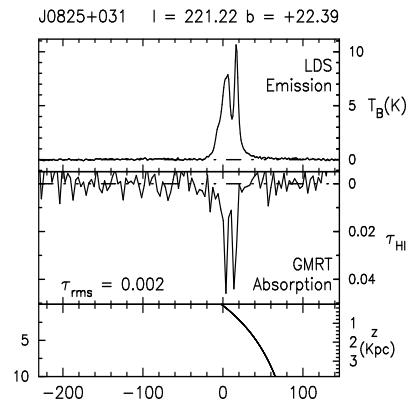

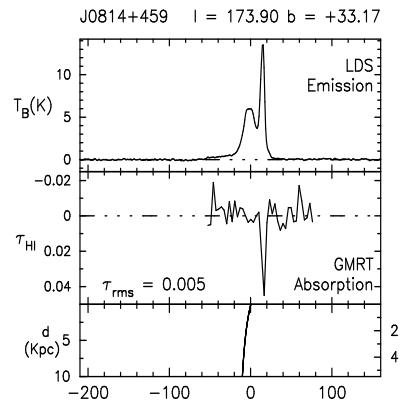

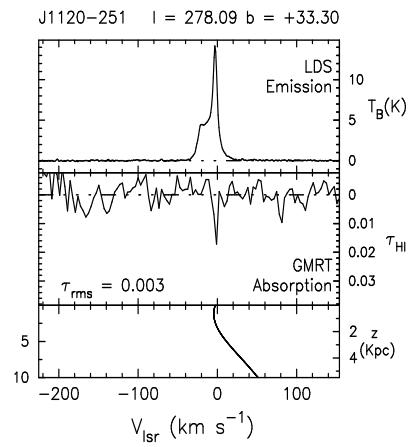

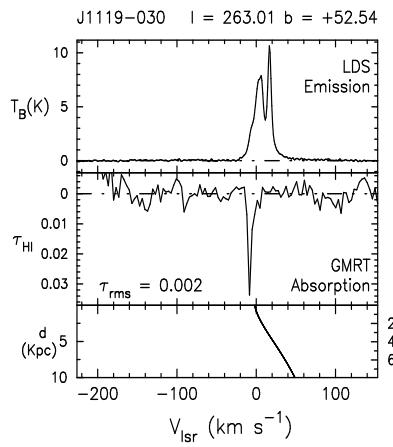

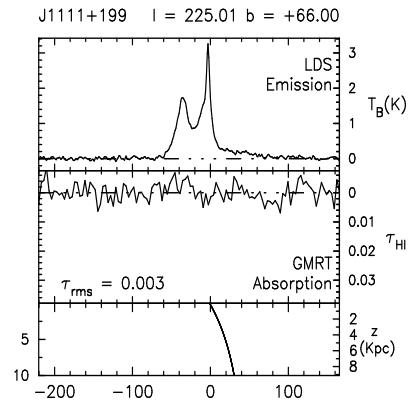

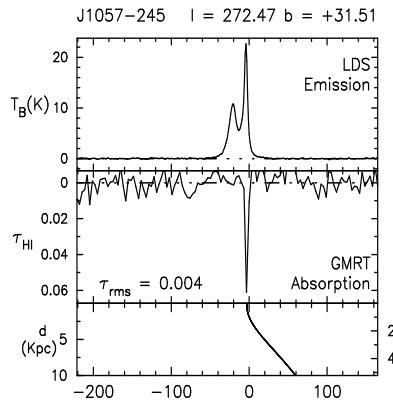

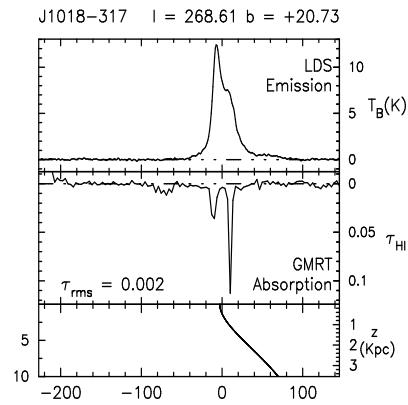

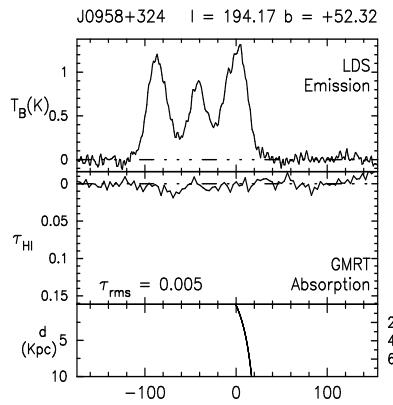

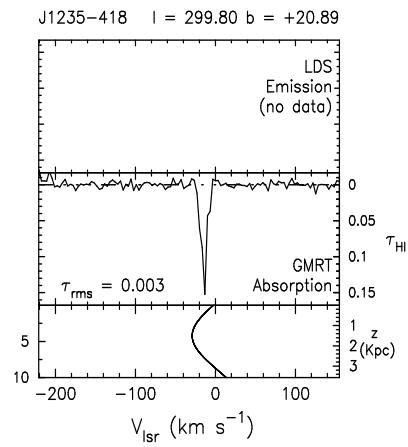

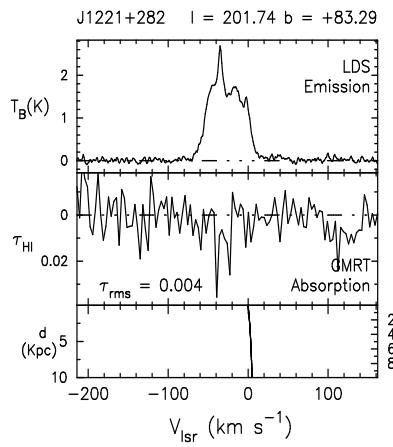

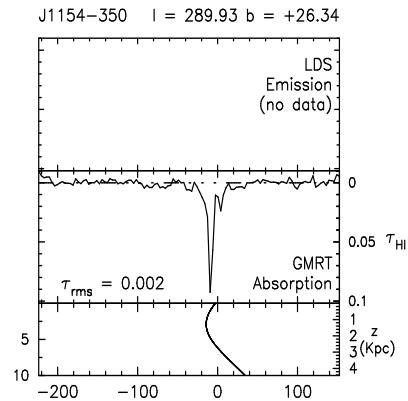

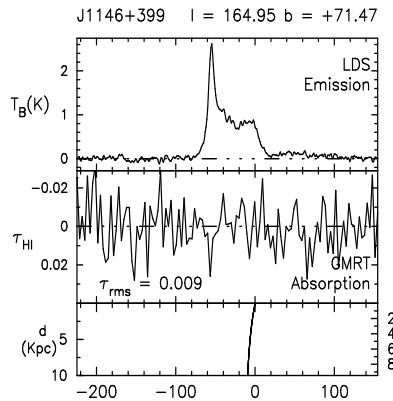

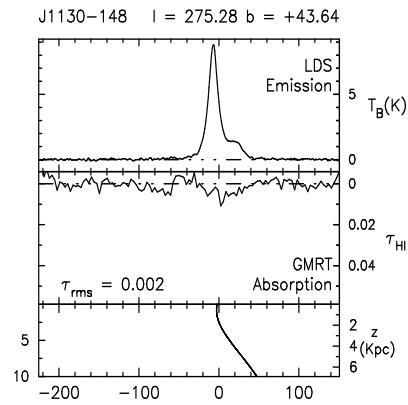

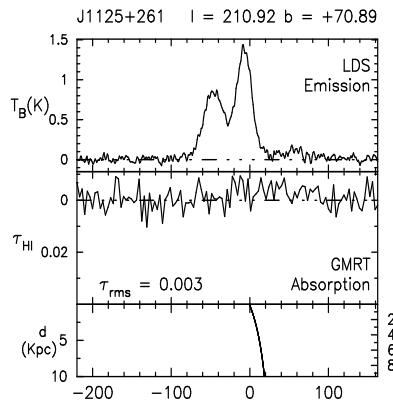

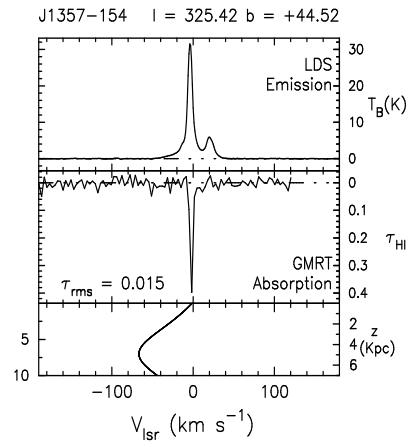

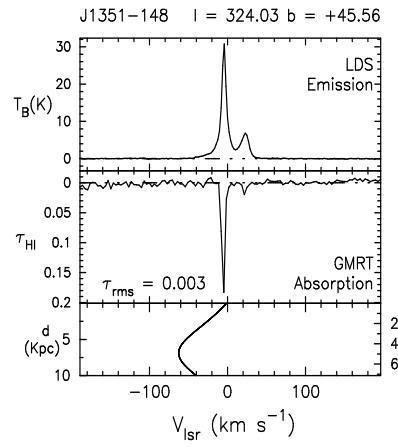

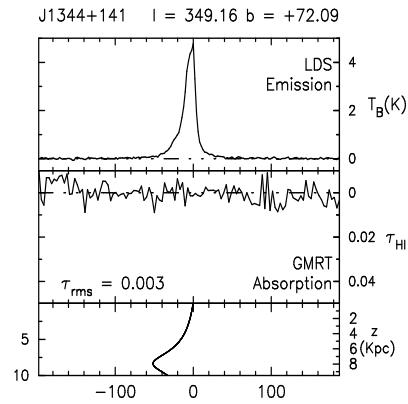

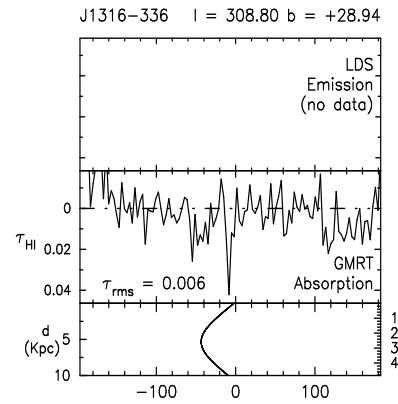

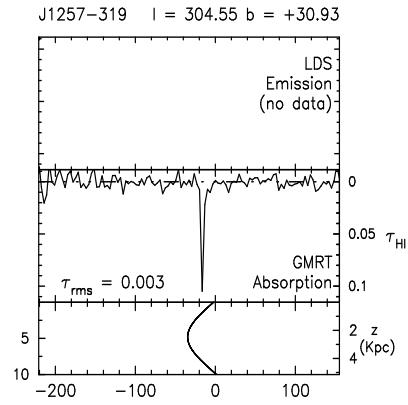

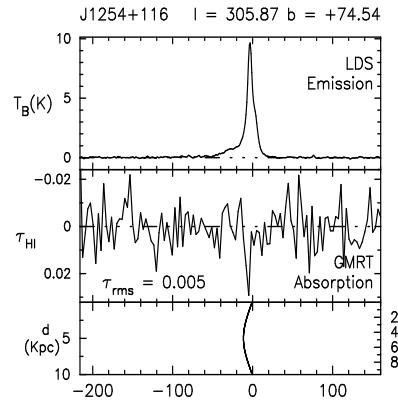

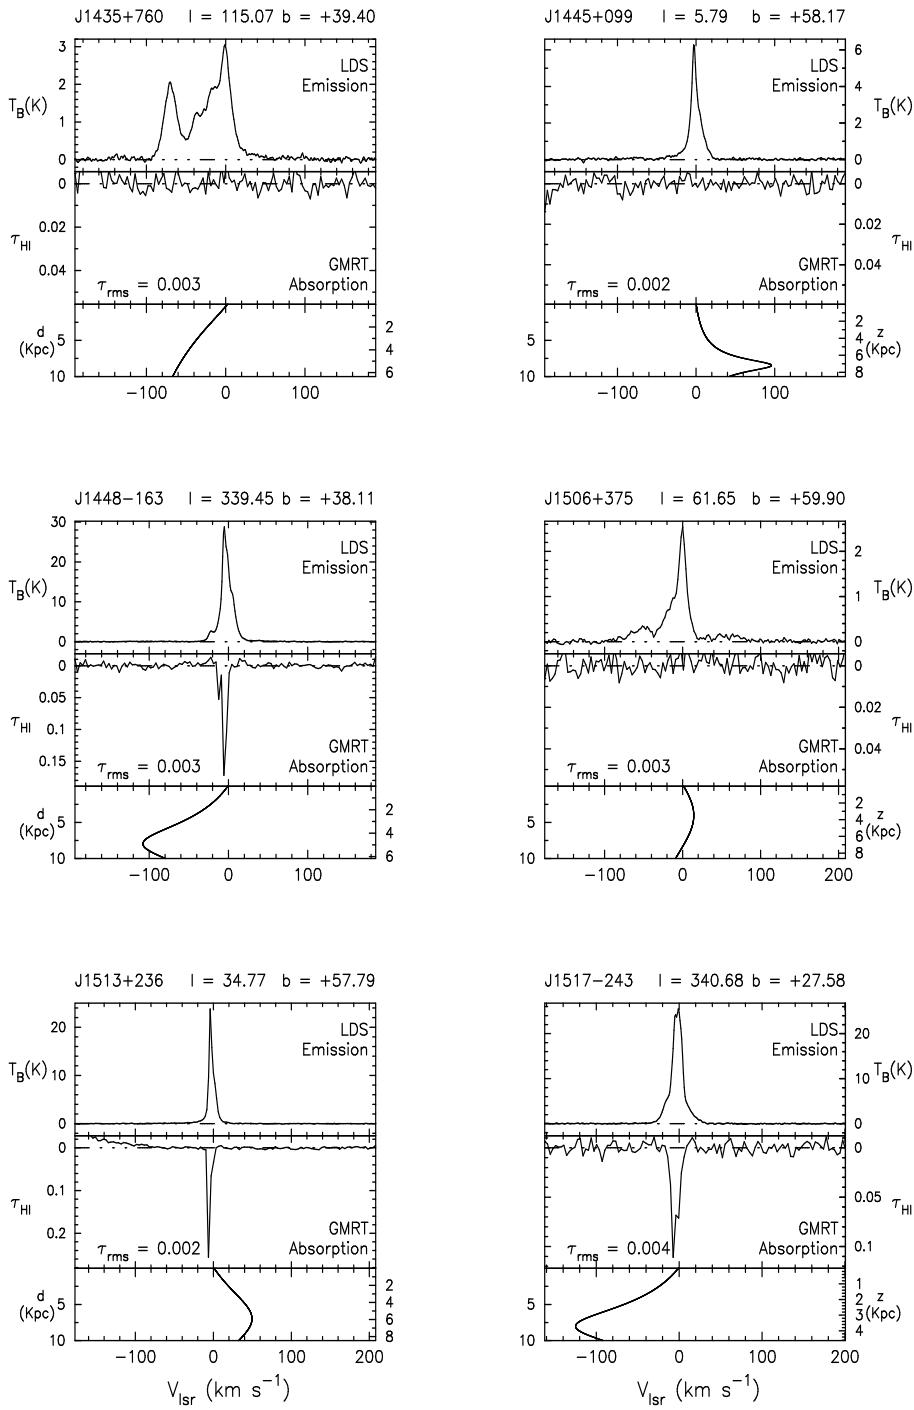

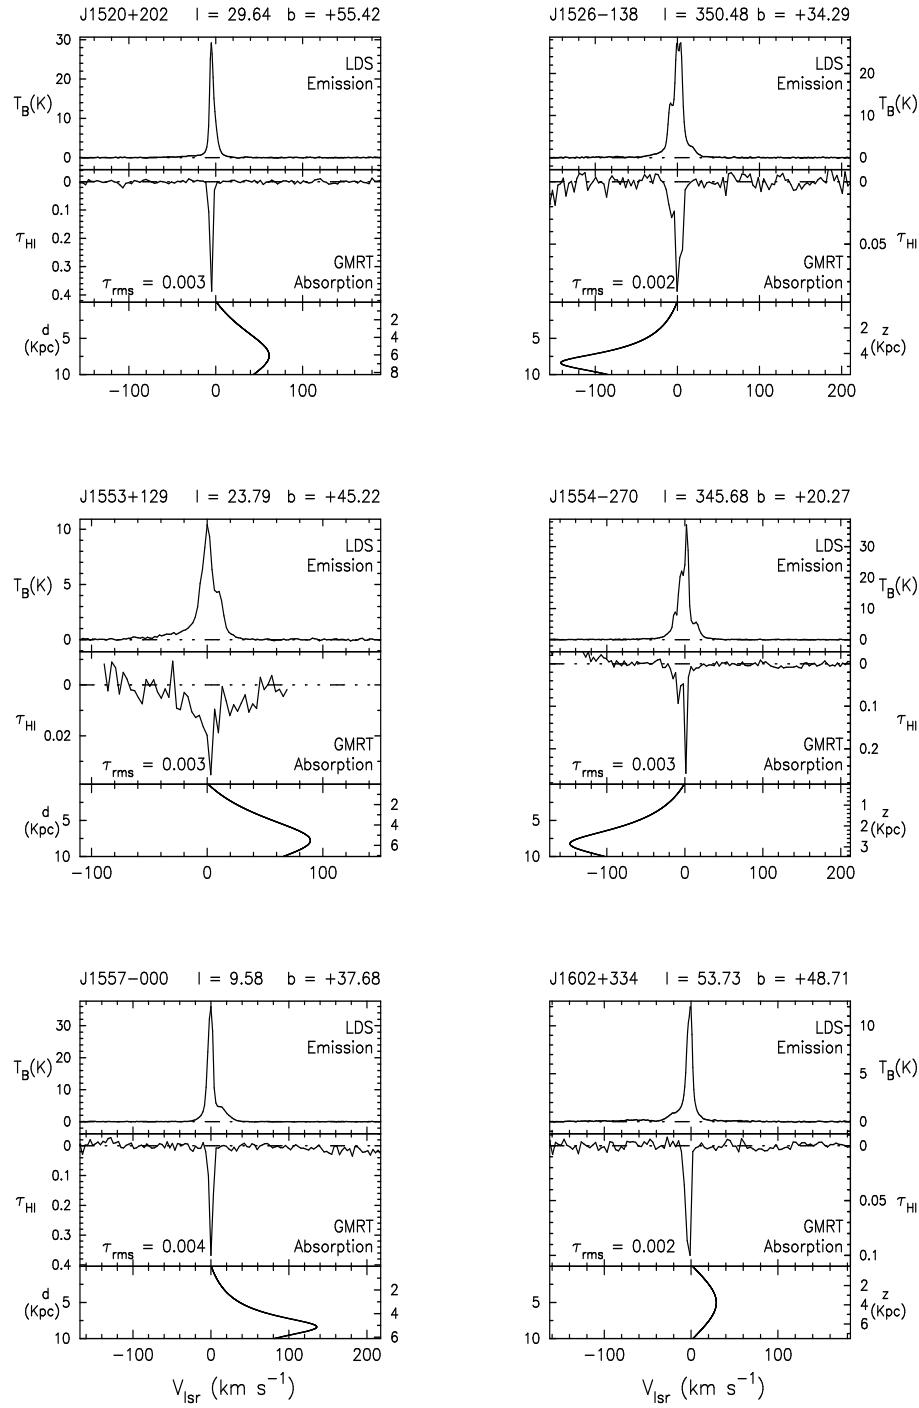

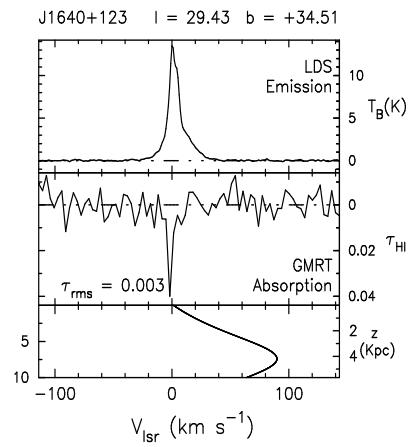

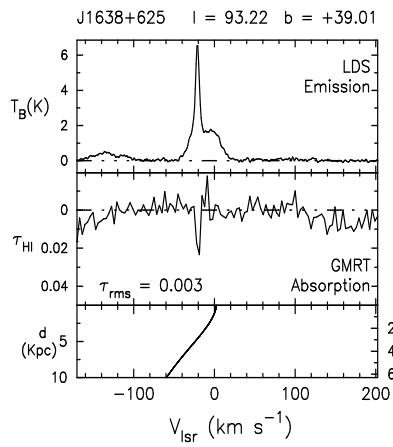

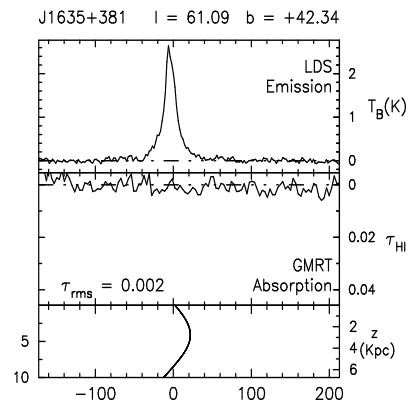

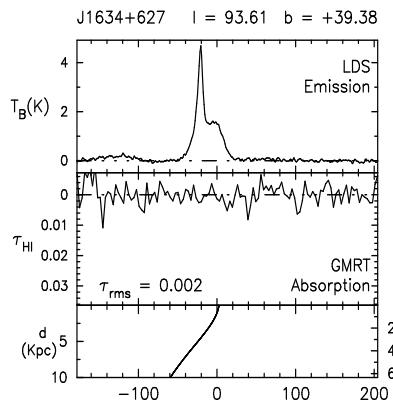

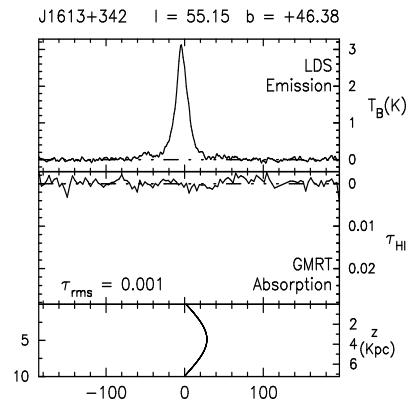

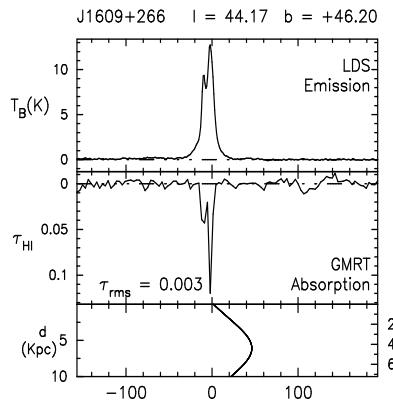

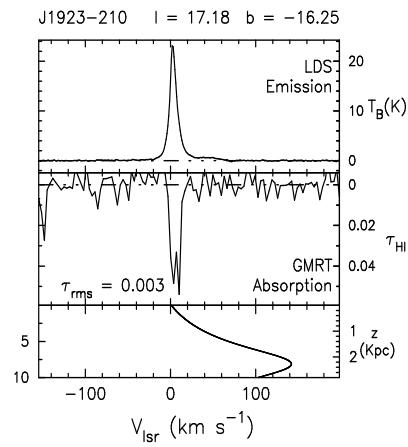

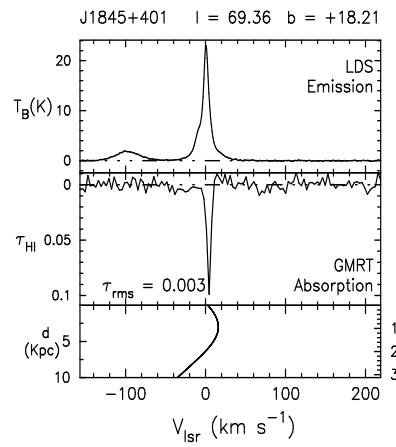

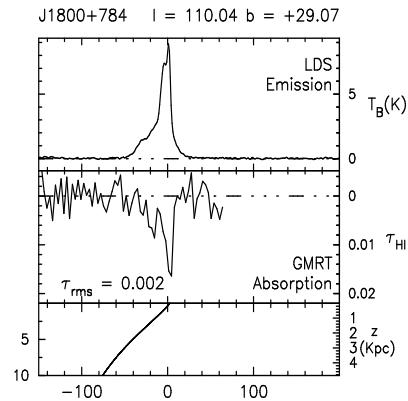

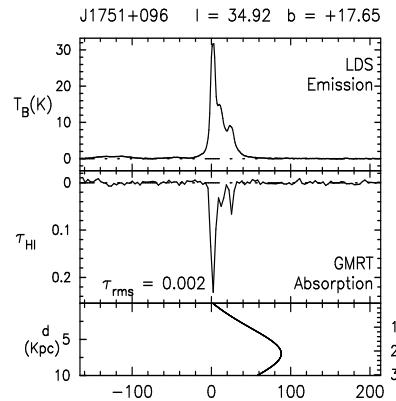

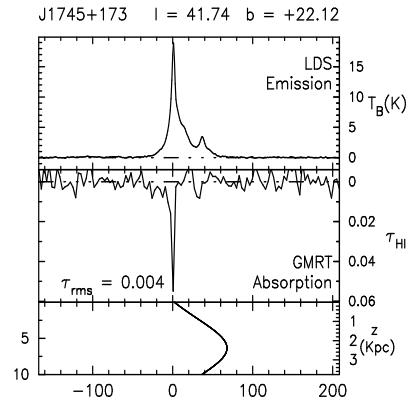

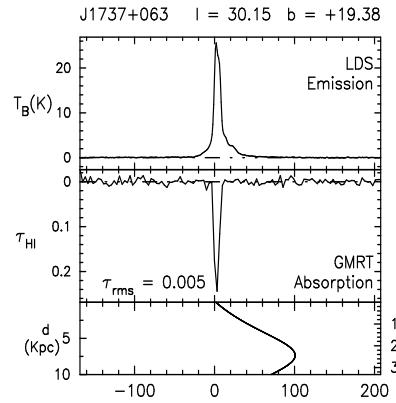

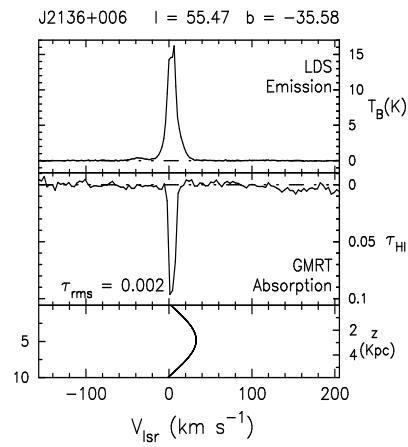

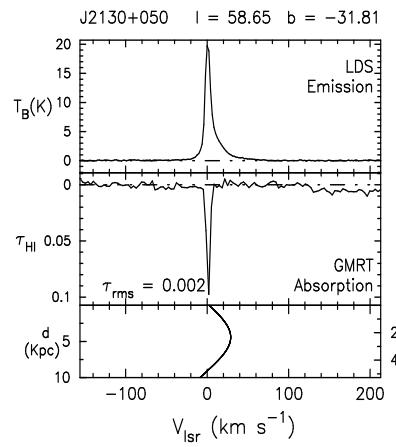

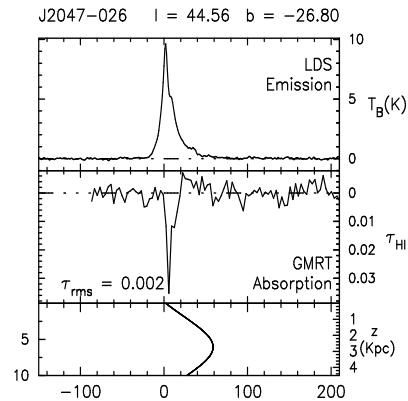

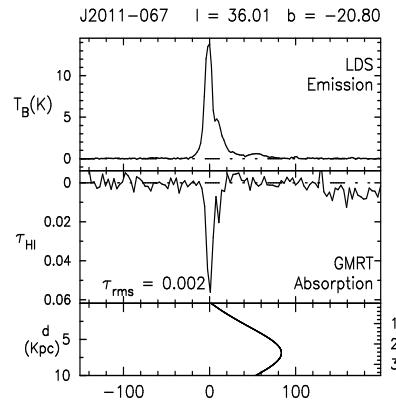

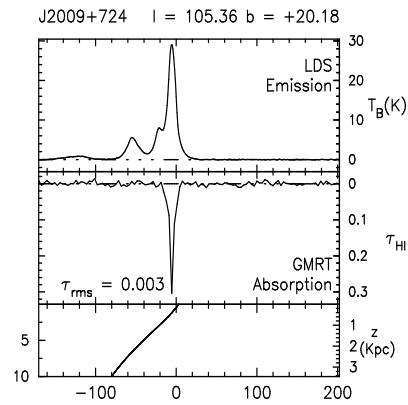

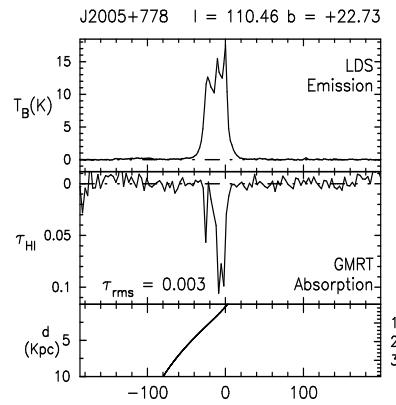

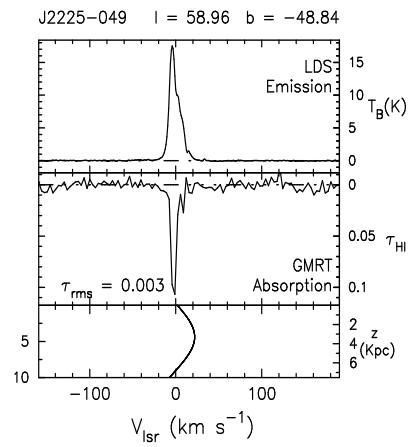

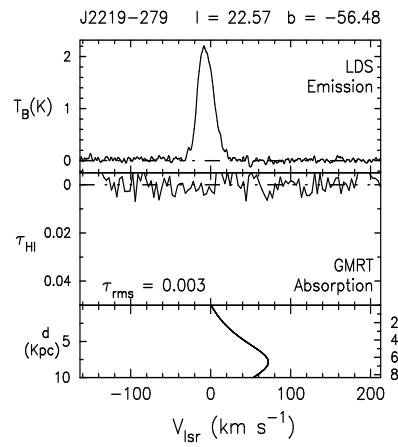

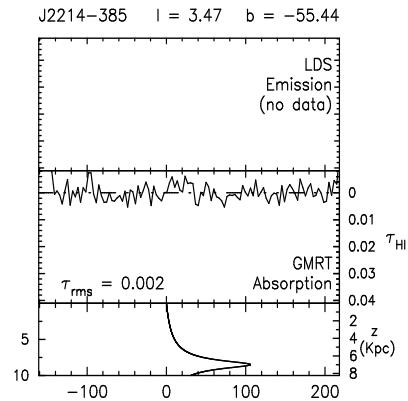

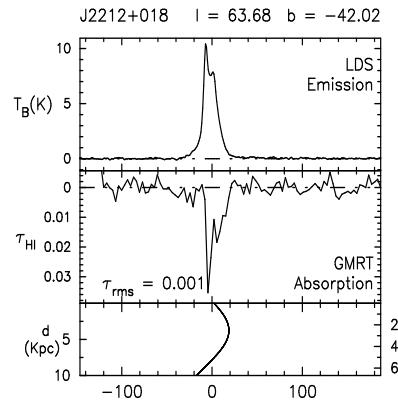

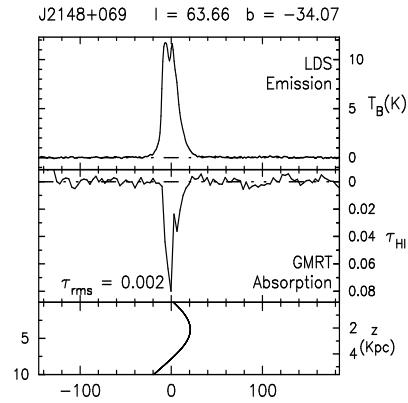

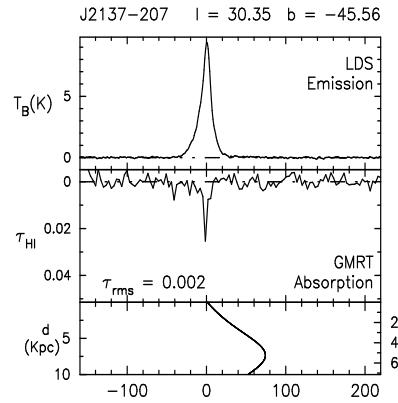

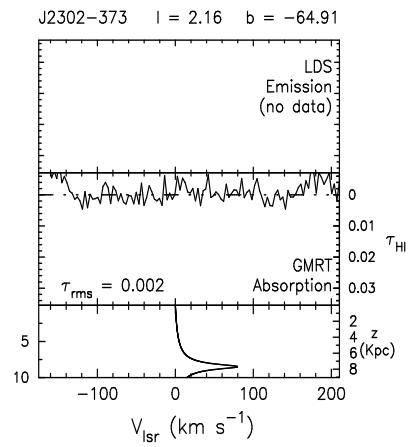

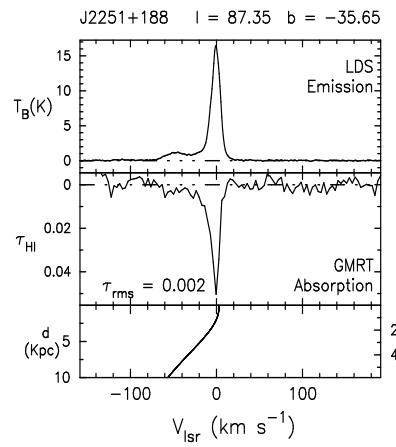

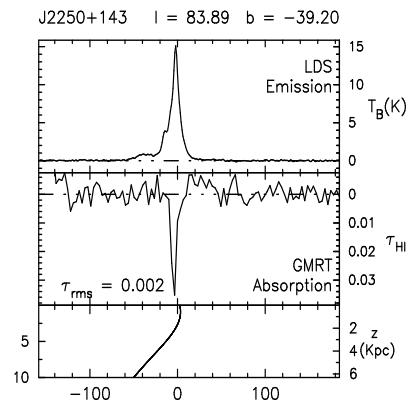

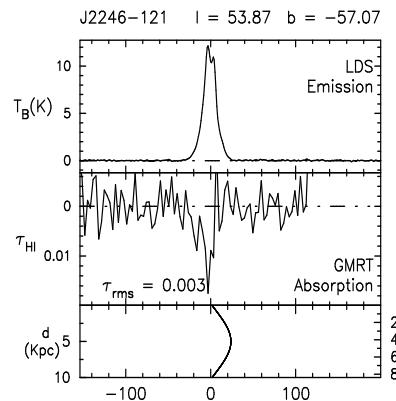

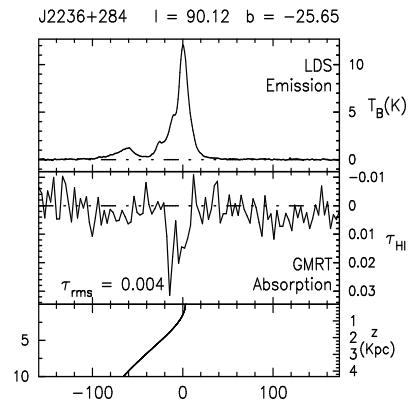

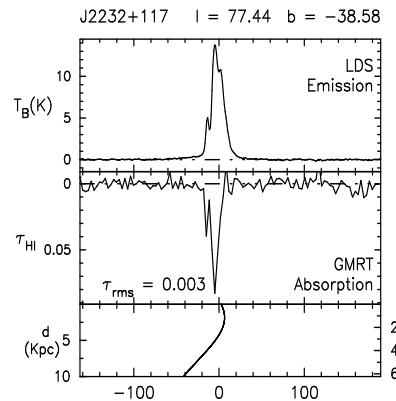

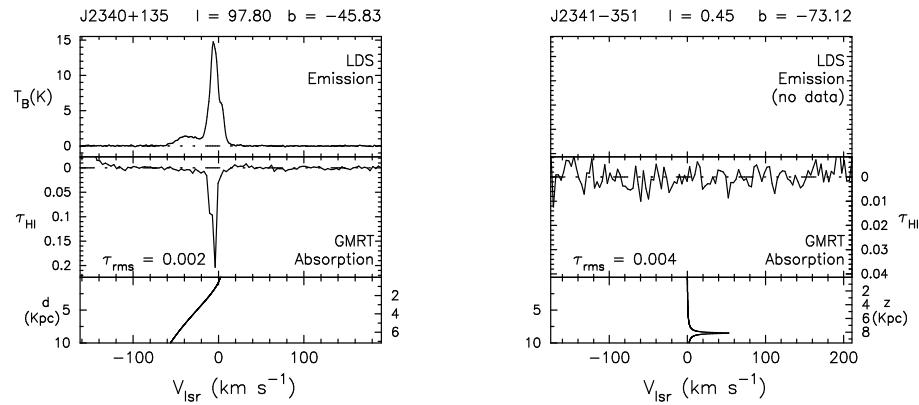

## Appendix C

In this Appendix, we list the discrete HI features identified from the high latitude Galactic HI absorption survey using the GMRT and from the HI emission data along the respective lines of sight from the Leiden-Dwingeloo survey of Galactic neutral hydrogen. We have used the HI emission and absorption data to estimate the spin temperature of the absorbing gas.

In the following table, the first column lists the name of the background source, towards which the absorption was measured using the GMRT. Columns 2, 3 and 4 list the peak optical depth, the mean LSR velocity and the FWHM respectively of discrete components identified using Gaussian fitting. The value of FWHM is deconvolved for a channel width of  $3.26 \text{ km s}^{-1}$ . The unresolved lines are marked with a “–”. Columns 5, 6 and 7 list the same for the HI emission profile along the same line of sight, obtained from the Leiden-Dwingeloo survey of Galactic neutral hydrogen (Hartman & Burton, 1995) The formal  $1\sigma$  errors estimated in the last digit of the fitted parameters are given within brackets. Column 8 lists the spin temperature, calculated using the absorption and emission data. Column 2 also lists the  $3\sigma$  optical depth limit obtained from the HI absorption profiles along the respective directions.
